A final report prepared for the Rural Industries R\&D Corporation

To control root-knot nematodes with the use of resistant cultivars or by rotation with non-host crops, it is necessary to identify the nematodes and their host ranges. However, traditional methods of identification are time-consuming, inaccurate and unreliable and most do not predict host range. More than 40 species have been described, some with more than one host race. The most common are M. javanica, M. incognita, M. arenaria and M. hapla causing $95 \%$ of the damage worldwide.

Workers in Australia and overseas have detected a wide variety of DNA markers in an effort to differentiate species and races. However, with few exceptions, these studies compared only a small number of isolates. It is questionable whether those populations were characteristic of variation found in the field. The study requires a population genetics approach, with analysis of the distribution of molecular polymorphism within and among field isolates.

We have paid particular attention to polymorphisms in mitochondrial DNA (mtDNA) because of the large copy number of the mitochondrial genome, its small size, rapid evolutionary rate, ease of extraction and because the entire mitochondrial genome of Meloidogyne javanica has been sequenced.

We have examined a large number of Australian populations of Meloidogyne and characterised them by perineal pattern, standard host range, esterase phenotype and RFLP's of mtDNA. Using RFLP's of mtDNA, we have found 10 different mtDNA types, some of which correspond to those found by workers in the USA. We have also found additional mtDNA types. Esterase phenotypes corresponded perfectly with mtDNA type. Perineal pattern was not correlated with mtDNA type. Host range was reasonably well correlated with mtDNA type but there was a significant number of discrepancies. Also, we have found several novel host reactions which do not correspond to any known species or race.

Previous work by researchers in USA suggested greater than $3 \%$ sequence divergence between M. javanica, M. incognita and M. arenaria. However, our studies show less than $0.6 \%$ sequence divergence between these species. Nevertheless, there is more than $2 \%$ sequence divergence within M. hapla and more than $24 \%$ between M. hapla and the other species.

The standard host range test uses five hosts and only two reaction categories (resistant and susceptible) to represent the range of reactions of these species and races on more than 2,000 plant species. Reactions are often intermediate so the classification system forced populations into artificial groupings which may not have agricultural relevance. We propose that a host range test should use only extreme resistant and susceptible reactions.

Initial data show that some soybean cultivars, unlike the standard host range test, could distinguish between $M$. arenaria race 2 and $M$. javanica and between two host range types of haplotype D (M. javanica). These will be tested across a large number of populations of each haplotype.

We suggest that further studies of these nematodes should focus on well-defined molecular groups, whether or not these coincide with existing
taxonomic units. The aim of a host range test is to corroborate molecular differences. Where genetic differences occur, we need to show that these correlate with significant host range differences. Similarly, where host range differences occur, we must identify genetic differences to be able to distinguish different host races.

We have devised a PCR-based diagnostic for the mtDNA haplotypes identified so far. This is a simple test involving DNA amplification and RFLP analysis of the product. This test should be extended to differentiate further host races and for use with soil and root samples.

## (iii) BACKGROUND

Root-knot nematodes are major pests of many agricultural and horticultural crops. Collectively, the various species of root-knot nematode affect nearly every agricultural, horticultural and ornamental crop grown (Table 1). Not only are yields affected but the quality and marketability of crops is also reduced. This nematode is currently estimated to cause crop losses of 5-20\% under present control strategies, which usually depend on chemical nematicides (Bird 1978; O’Brien and Stirling 1991). Many of these chemicals are under threat because of health and environmental risks and efficacy problems and their high cost restricts their use to high value crops. We cannot assume that nematicides currently used will be available in the future.

Table 1. Crops affected by root-knot nematode in Australia.

Tree and vine fruits
almond, grape, kiwifruit, nectarine, passionfruit, pawpaw, peach, plum
Vegetables
bean (mung, French, navy), beetroot, capsicum, carrot, celery, cucurbits (cucumber, melon, pumpkin), eggplant, lettuce, okra, onion, potato, sweet potato, tomato
Ornamentals
carnation, Chrysanthemum, Dahlia, gerbera, gladiolus, Protea, rose Field crops aloe vera, clover, cowpea, kenaf, lucerne, lupin, pigeon pea, peanut, soybean, sugarcane, tea, tobacco
Other horticultural crops
banana, ginger, pineapple, strawberry

Nematicides control all species and races of root-knot nematode but many non-chemical control methods are species-specific. To use sustainable management systems for root-knot nematodes based on crop rotation, resistant cultivars and biological control agents, it is necessary to detect and identify nematodes in root and soil samples. Current methods using
morphological features (Jepson 1987) and a standard host test (Eisenback et al. 1981) are insensitive, inaccurate and time-consuming. A molecular diagnostic would enable rapid and accurate detection and identification of root-knot nematodes in soil and root samples which would facilitate management recommendations.

## (iv) OBJECTIVES

(a) To identify root-knot nematode species in a collection of single eggmass cultures from throughout Australia by traditional methods.
(b) To assess the genetic variation within and between the species of root-knot nematode in the culture collection.
(c) To compare the host ranges of different species and genetic races within a species of root-knot nematode.
(d) To develop a rapid and reliable genetic method for diagnosing species and races of root-knot nematode from soil samples and infected roots.

## (v) INTRODUCTORY TECHNICAL INFORMATION

Identification of species of root-knot nematode has for many decades relied on morphological characters (Jepson 1987). The main character used has been the perineal pattern (i.e. the pattern of striae on the cuticle around the vulva and anus of the adult female). Although there are typical patterns for each of the four most common species, variability makes it unreliable. Other morphological characters include measurements of various structures. The most diagnostic appear to be the length of the female stylet, the distance from the head to the excretory pore, width of vulva, distance from anus to vulva and length of the tail of the second-stage juvenile. However, there is great variability and overlap of these measurements between species.

Esterase phenotype has been a useful character for differentiating some species (Esbenshade and Triantaphyllou 1990). Although morphological characters and esterase phenotypes may distinguish some species, they cannot differentiate host races within species. Furthermore, the standard host range test cannot distinguish between $M$. javanica and M. arenaria race 2 .

Powers and Sandall (1988) found considerable variation in mtDNA restriction fragment patterns within and among 12 isolates representing different species and host races of Meloidogyne and this provided the basis for a subsequent assay using the polymerase chain reaction (PCR) and diagnostic HinfI polymorphisms (Harris et al. 1990). However, the data obtained had some significant limitations. A small number of isolates were examined and some of these were misidentified (Hyman and Powers 1991) resulting in an overestimate of within-species variation. Moreover, the analyses of wholegenome restriction fragment variation (Powers and Sandall 1988; Powers et al. 1986) were potentially confounded by insertion/deletion events.

The analysis and use of RFLP's is greatly enhanced when the variable sites can be located, either by restriction site mapping or by reference to a sequence. The complete nucleotide sequence of a M. javanica mtDNA has been determined (Okimoto et al. 1991; D. Wolstenholme pers. comm.). This genome (Figure 1) contains the same number of proteins, rDNA and tRNA genes as other nematode mtDNA's but is distinguished by an apparently noncoding region of about 7 kb that includes $\sim 36$ copies of a 102 bp sequence and $\sim 11$ copies of a 63 bp sequence. Okimoto et al. (1991) also reported variation in the sizes of the repeat-containing restriction fragments among mtDNA from different races and species of Meloidogyne. They suggested that these differences, most likely caused by variation in repeat copy number, may provide a useful diagnostic tool.

Harris et al. (1990) were able to differentiate three haplotypes of Meloidogyne using HinfI digestion of a 1.8 kb amplified product of the cytb gene and an intergenic region. However, this test did not distinguish between M. hapla and $M$. javanica and no amplification was obtained for some populations of M. arenaria. This lack of amplification was resolved by a further primer located in the 16srDNA (T.O. Powers pers. comm.). Powers and Harris (1993) reported a test to differentiate between five haplotypes corresponding to M. incognita, M. javanica, M. arenaria, M. hapla and M. chitwoodi. This used an amplification product of the COII and 16srDNA genes and digestion with DraI and HinfI.

## (vi) RESEARCH METHODOLOGY

Nematode populations were selected from the QDPI root-knot nematode collection which now contains over 100 single eggmass populations from throughout Australia. Eggs were removed from roots in $0.5 \%$ sodium hypochlorite (Southey 1986) for DNA and host range studies. Females were extracted from roots by shaking in $5 \%$ Clariphase ${ }^{(\mathrm{R})}$ (containing pectinolytic enzymes) overnight. Twenty females of each population were examined (Jepson 1987) for perineal pattern, stylet length and position of excretory pore. Females for esterase studies were dissected by hand from roots. Esterase phenotypes were determined by the method of Esbenshade and Triantaphyllou (1985). Total and mitochondrial DNA were prepared from eggs as described in Dowling et al. (1990) except that eggs were homogenised by hand with mortar and pestle for 5 min before centrifugation.

The standard host range test is described by Taylor and Sasser (1978). Plants were inoculated with 6,000 eggs each with treatments replicated four times. The host plants used were Capsicum frutescens L. (capsicum) cv. California Wonder, Gossypium hirsutum L. (cotton) cv. Deltapine 16, Arachis hypogaea L. (peanut) cv. Florunner, Lycopersicon esculentum Mill. (tomato) cv. Tiny Tim, Nicotiana tabacum L. (tobacco) cv. NC95 and Citrullus vulgaris Schrad. (watermelon) cv. Charleston Gray. After 60 days, roots were washed and stained with $0.15 \%$ phloxine B to highlight eggmasses.

The standard host test uses eggmass ratings according to the following scale: 0 $=0$ eggmasses per plant, $1=1-2,2=3-10,3=11-30,4=31-100$ and $5=$ $>100$. If more than 100 eggmasses were found, no more were counted. In the standard differential host test, plants with average ratings of 2 or less are classified as resistant and those with ratings greater than 2 are classified as

Figure 1. Positions of ten polymorphic restriction enzyme sites and a 529 bp deletion on the Meloidogyne mitochondrial DNA moleculae (bottom) aligned with the gene map that also shows the positions of the 63 bp and 102 bp tandem repeats. The deletion in haplotype A is shown as a box and encompasses EcoRI, HindIII and MboI sites.

susceptible. The reaction of each population to the six hosts is used to assign a species and race (Table 2).

Further information on host range was obtained by screening large numbers of plant genotypes with selected nematode populations to identify possible sources of resistance in plants easily grown in the glasshouse. Firstly, four nematode populations representing haplotypes A, B and D were tested against 50 plant genotypes (Table 3). This revealed possible differences within soybean and cowpea. These, along with other plant genotypes, were tested for resistance to five nematode populations representing haplotypes A, $\mathrm{B}, \mathrm{C}$, and D and another population with haplotype D but with the type 2 novel host range (Table 4). Populations of M. hapla were tested against cultivars of crops with potential for variation in resistance (Table 5).

MtDNA haplotypes were initially identified from RFLP's produced by digestion with EcoRI, DraI, MboI, HindIII and separation of end-labelled fragments on $1.5 \%$ agarose and $3.5 \%$ polyacrylamide gels (Hugall et al. 1994). Later, the complete restriction map of mtDNA of M. javanica (D. Wolstenholme pers. comm.) and high resolution gels were used to identify all restriction sites. Primers designed from the $M$. javanica sequence (D. Wolstenholme pers. comm.) (Table 6; Figure 2) and other primers (Harris et al. 1990; Powers, T.O. pers. comm.) were used to sequence the tRNA ${ }^{\text {His }}$, $16 \mathrm{srDNA}, \mathrm{ND} 3$ and $5^{\prime}$ end of $c y t \mathrm{~b}$ genes. This provided 2161 bp of sequence from representatives of haplotypes $\mathrm{A}, \mathrm{B}, \mathrm{C}, \mathrm{D}, \mathrm{G}$ and H .

A 1.8 kb fragment, identified as the M. hapla homologue to that sequenced in haplotypes A, B, C, D, G and H (16srDNA, ND3, cytb), was cloned from population 113 and sequenced. From this, primers were designed to amplify and sequence this region in all M. hapla populations (populations 48, 102, 113, 114 and 150). A 102 bp tandem repeat of population 113 of M. hapla 113 was characterised by sequencing. Nuclear rDNA was assessed for representatives of haplotypes by sequencing the ITS/5.8srDNA and intergenic spacer (IGS) regions using conserved primers.

## (vii) DETAILED RESULTS

Perineal pattern was poorly correlated with other characters measured (Table 7). Host range was reasonably well correlated with esterase phenotype and mtDNA haplotype but there were significant discrepancies and the appearance of novel host range types (Table 8). Other morphological measures (Table 9) did not correlate well with perineal pattern, host range or biochemical characters.

Initial screening identified soybean and cowpea as possible sources of variation in resistance and were easily grown in the glasshouse. Further screening showed that reproduction on four cultivars of soybean, cvs. Dragon, Manark, Forrest and Triton, could differentiate the haplotypes of M. arenaria race 2 and M. javanica. It confirmed the difference between novel host range type 2 and other standard host ranges (Table 4).

Sequence divergence between haplotypes, other than those corresponding to M. hapla, was less than $0.6 \%$ (Figure 3). Sequence divergence between populations of $M$. hapla were greater than $2 \%$ while divergence between the

M. hapla group and the other haplotypes was more than $20 \%$ (Table 10 ; Figure 4). Several restriction sites are concentrated around $\mathrm{tRNA}{ }^{\text {His }}$ to cytb (Figure 1). In M. arenaria and M. hapla, there is a deletion immediately $5^{\prime}$ to tRNA ${ }^{\text {His }}$. This deletion is 529 bp in M. arenaria, much larger in M. hapla and contains several restriction sites. In two cases, a single nucleotide substitution causes more than one change in restriction sites.

The mtDNA of Meloidogyne contains a region of tandem repeats of a 102 bp sequence. M. hapla has a larger mtDNA genome (25-27 kb compared with $\sim 20 \mathrm{~kb}$ in $M$. javanica) than the other species due to longer non-coding regions with greater duplication of tandem repeats. Some populations of $M$. hapla also contained a possible 1.3 kb duplication. There was no obvious relationship between the sequences of the 102 bp repeats in M. hapla and M. javanica. Within population 113 of M. hapla, there was about $5 \%$ length difference and about $5 \%$ sequence difference between repeats.

MtDNA haplotypes could be distinguished by restriction analysis of PCR amplification products (Table 11). Amplification using the primers, MLSR and MCYTB, and digestion with HinfI distinguishes M. hapla and haplotypes $\mathrm{B}, \mathrm{D}$ and (A, C and G). A size difference in the amplification product using MORF and TRNAH distinguishes haplotype A from C and G.

Amplification with MLSR and MCYTB and digestion with MnlI distinguishes (M. hapla and haplotype B), C and (A, D and G). Size differences in the MORF-TRNAH product distinguishes haplotype $A$ from $D$ and $G$. Haplotypes D and G can be distinguished by digestion with AflIII. M. hapla can be distinguished from haplotype B because it does not amplify with MORF-TRNAH. Simultaneous amplification with these two primer sets may provide a simpler test.

To distinguish different haplotypes of M. hapla, the MLSR-CYTB product may be cut with AseI or DraI. This distinguishes haplotypes F and I from E and J. These two groups may correspond to the cytogenetic races A and B.

Studies of the ITS region of 5.8 srDNA were complicated by multiple loci and hybrid polyploidy. However, the results were consistent with mtDNA haplotypes. Results of studies in a 600 bp region of the IGS between 5 srDNA and 18 srDNA were easier to interpret and were consistent with mtDNA groupings. Haplotypes A, C and D were identical, haplotype B was very slightly divergent ( $<0.5 \%$ ) while M. hapla was very divergent with two main types corresponding to populations 113 and 114.

## (viii) DISCUSSION

Of a total of 662 populations collected worldwide in a previous study, about $47 \%$ were M. incognita, $40 \%$ M. javanica, $7 \%$ M. arenaria and $6 \%$ M. hapla (Taylor et al. 1982). In the current study, we found a similar distribution of populations when using the standard host test. However, we also found that $14 \%$ of populations induced host reactions which were novel, i.e. an identity could not be based on the standard host test.

The main constraint on achieving all of the original objectives has been the lack of traditional methods to identify populations accurately. Furthermore,

Figure 4.
A, Relationships between Meloidogyne spp. based on $\sim 2000 \mathrm{bp}$ of mtDNA; B, Divergence of M. javanica from M. hapla relative to Ascaris suum and Caenorhabditis elegans based on 16s rDNA. Values indicate relative difference.

${ }^{\mathrm{b}}$-, nucleotide deleted
${ }^{\text {c }}+,-$; gain and loss of site, respectively.
during this project, we have revealed that overseas work was misleading because only a few populations representative of species and races were used and molecular differences between populations had been overestimated and because some of their populations had been misidentified. Our mtDNA groupings are corroborated by other genetic data, e.g. esterase phenotype. However, these molecular groupings conflict with identification of species and races by the standard host range test leading us to question the validity of the existing taxonomy.

The standard host range test, which was developed in the USA has been used for 40 years to provide a preliminary indication of nematode identity. The main disadvantage of the standard host range test is that it forces populations into artificial groups based on numbers of eggmasses on plants. There are further potential sources of error when assessing low numbers of eggmasses. The test also does not cope with species other than the four most common, such as $M$. hispanica and other variations as exhibited by the novel reactions, although novel reactions may represent rare species.

In this study, cotton was resistant and tomato susceptible to all root-knot nematode populations. Therefore, in effect, only four plant genotypes were being used to differentiate several species and races of Meloidogyne. It is probably an oversimplification to assume that the reactions of even the four most common Meloidogyne species and their races on four plant cultivars represent the total pathotype variability, especially as this genus is known to attack more than 2000 plant species. If the set of differentials were expanded, more differences among populations should be demonstrated. Our work suggests that some soybean cultivars may be useful for further differentiation of molecular groupings.

The standard host test was poorly correlated with perineal pattern, indicating that morphology was not a reliable indicator of pathogenicity. Hugall et al. (1994) suggest that further molecular groupings are required in haplotypes A and D to be consistent with the standard host test. Similarly, further host range data are required in these haplotypes so that pathogenicity is consistent with molecular groupings. We propose to assign plants with up to 5 eggmasses as resistant and more than 30 eggmasses as susceptible and not to assign intermediates to groups. A more useful host test could be devised by concurrently determining molecular groupings of populations and the host range of these groupings in the cropping systems of interest. Then it would be possible to predict control strategies based on crop rotation and resistant cultivars.

There is very low divergence between and diversity within haplotypes A, B, C, $\mathrm{D}, \mathrm{G}$ and H . This, together with no discernible phylogenetic order between haplotypes and essentially fixation of esterase phenotype with mtDNA haplotypes (except in haplotype A), is explained by recent independent parthenogenetic origins of each haplotype from minor variants of the same female lineage. M. hapla, however, has a distinct female lineage. It appears that M. hapla has the ancestral gene order. M. javanica, M. incognita and M. arenaria have insertions and rearrangements of this gene order with subsequent deletion in M. arenaria.

Previous studies reported much greater sequence divergence between $M$. javanica, M. incognita and M. arenaria than did this study because they were
misled by length variations not due to nucleotide changes, the deletion in haplotype A and the multiple restriction site changes caused by single mutations. Our degree of error is much less also because we used higher resolution gels which distinguish more restriction sites. The wide divergence of M. hapla from the other species is consistent with other molecular data for nuclear genes e.g. allozyme and nuclear repeat studies. Our studies have also quantified divergence. Previous mtDNA studies confused the relationship between M. hapla and the other species because they lacked resolution and detail and because some populations had been misidentified.

## (ix) IMPLICATIONS AND RECOMMENDATIONS

A polymerase chain reaction-based diagnostic test is now available to identify major molecular groups of Meloidogyne. These groups are generally related to host range. However, more work is needed to corroborate molecular grouping and to make these consistent with host range groups. Progress is now being made towards subdividing molecular groups using nuclear ribosomal DNA and RAPD studies. We also need to explore agriculturally relevant attributes of molecular groups by assessing an extended group of differential hosts.

When a diagnostic test is available to predict host range, this will catalyse the use of non-host rotation crops and resistant cultivars to control root-knot nematode. Industries threatened by severe yield losses due to lack of suitable chemical nematicides will then be able to rely on more sustainable management strategies.

## (x) DESCRIPTION OF INTELLECTUAL PROPERTY

This project has not produced developments of immediate commercial significance. However, it is possible that a PCR-based diagnostic test may be commercialised.

## (xi) TECHNICAL SUMMARY

As a result of this project, techniques for DNA preparation have been refined and used to isolate mtDNA and nuclear DNA from eggs of the root-knot nematode collection. Standard techniques for DNA analysis have been modified and refined for routine use with root-knot nematode DNA.

The root-knot nematode collection contains more than 100 populations from throughout Australia. Of these populations, 74 have been characterised by standard host range, 89 by perineal pattern, 69 by morphometric data, 51 by esterase phenotype and 66 by mtDNA restriction site variants. This has divided the collection into ten molecular groupings. Esterase phenotype is a character in addition to the original objectives set but has been found to correlate well with molecular groupings. Morphometric data and perineal pattern have been found to be too variable to be of use and will not be continued.

Previous studies revealed substantial variation in mtDNA apparently due to restriction site changes and variation in copy-number of 63 bp and 102 bp tandem repeats, but were hampered by small sample sizes and, in one case, misidentified specimens. We have extended the analysis of Meloidogyne mtDNA by (i) examining restriction site polymorphisms among a large number of Australian populations that have also been characterised for perineal pattern, standard host range and esterase phenotype, (ii) using higher resolution electrophoretic techniques and (iii) mapping variable restriction sites with reference to the complete nucleotide sequence. Our analysis reveals far less sequence divergence $(<0.6 \%)$ between variants than previously reported.

There was perfect correlation between mtDNA haplotype and esterase phenotype. In contrast, there were several discrepancies between traditional methods of identification and between these and either of the biochemical measures. Combined with the conceptual difficulties of delineating species among closely related parthenogenetic forms, our data suggest that further development of diagnostics for Meloidogyne should focus on well-defined genetic groups, whether or not these coincide with existing taxonomic units.

Amplification of mtDNA regions between the open reading frame (ORF) and the cytb gene and digestion with HinfI or MnlI will distinguish six molecular groups while digestion with AseI or DraI will differentiate two groups of $M$. hapla. In developing this, six new primers have been devised and more than 2000 bp of sequence for the ten haplotypes have been determined.

Progress has been made towards elucidating discrepancies between molecular groupings and host range by extending the host range test from the standard differential hosts. To date, 50 plant genotypes have been assessed for their ability to distinguish between different root-knot nematode types and several are of potential use. Four cultivars of soybean show promise in distinguishing haplotypes $\mathrm{A}, \mathrm{C}$ and D and in confirming differences in host range within haplotype D.

[^0]:    ${ }^{a}$ Reactions of host plants are listed in the following order: Capsicum frutescens (capsicum) cv. California Wonder; Gossypium hirsutum (cotton) cv. Deltapine 16; Arachis hypogaea (peanut) cv. Florunner; Nicotiana tabacum (tobacco) cv. NC95; Lycopersicon esculentum (tomato) cv. Tiny Tim; Citrullus vulgaris (watermelon) cv. Charleston Gray. An average eggmass rating of $<2$ indicates resistance ( R ); an average rating of $>2$ indicates susceptibility (S); plants with a rounded-off, numerical rating of 2 were assigned an $R$ or $S$ rating depending on whether the original value was $\leq 2$ or $>2$. For example, ratings of $1.5-2.0$ are considered indicative of resistance ( R ), ratings of 2.1-2.4 indicative of susceptibility (S).
    ${ }^{b}$ Significant ( $\mathrm{r}>0.811, \mathrm{P}<0.05$ ) when tested by correlation against standard host reactions i.e. ' + ' reactions in Table 1 were given a rating of 5 and ' - ' reactions a rating of 0 .
